

# Simulation

- Semantic analysis uses a combination of two techniques:

- **Tabulation**

Collection of declaration and contextual information into **tables** for easy lookup

- **Simulation**

Calculation of derived **attributes** by simulating the execution of the program on an ideal machine.

Two basic mechanisms are used to perform the simulation. These are the *Symbol Stack* and the *Type Stack*

Both of these stacks are similar to the run-time Expression Stack, but instead of computing the *value* of expressions, they are used to compute the attributes and types of expressions

# The Symbol Stack

- The **Symbol Stack** mimics the run-time resolution of references to symbols, mirroring the **Expression Stack**'s computation of symbol references such as subscripted variables
- Computes the *effective access attributes* of the reference, which may be different from the attributes of the declared symbols themselves

## Example:

If  $x$  is a variable field of a constant record  $r$ , then  $r.x$  is effectively a **constant**, not a **variable** (and therefore can't be assigned to)

- Programming languages vary widely in their rules for the effective attributes of complex symbol references - some are simple, some are very complex
- In general, we can say that the rule is that *minimum access* is inherited from left to right in a symbol reference - that is, a field cannot have greater access attributes than its parent

# Symbol Stack - Access Calculation Example

Consider the [Euclid](#) programming language reference

*M.R.X*

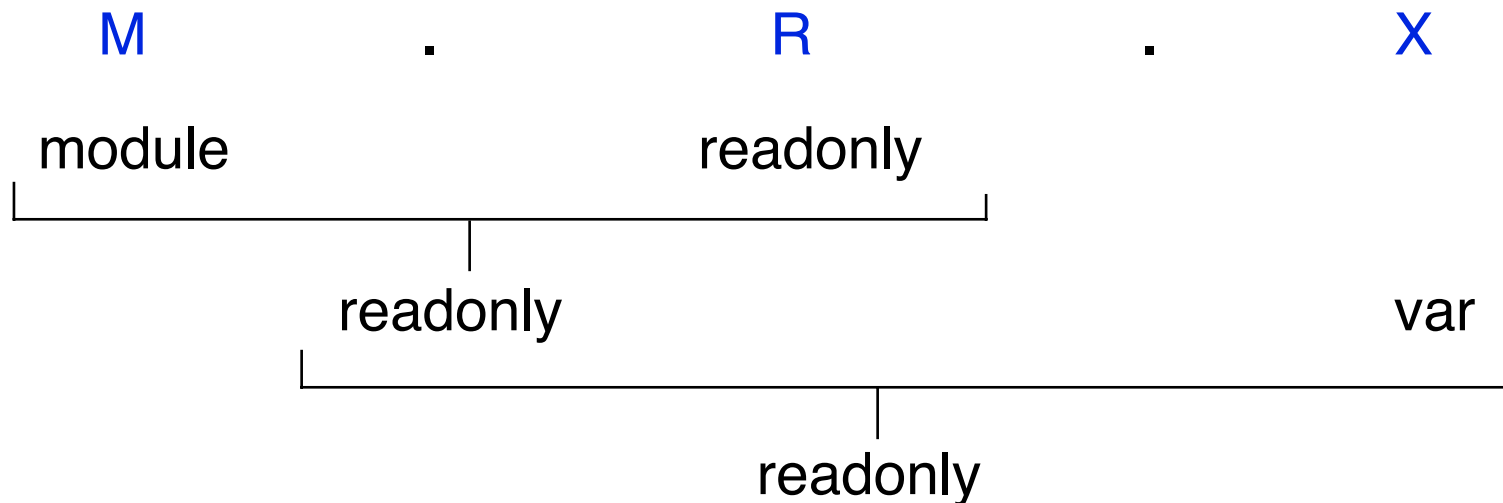

where

*M* is a module (i.e., static class)

*R* is a record variable exported **readonly** from *M*  
(i.e., is public but not assignable)

*X* is a **var** field of the record

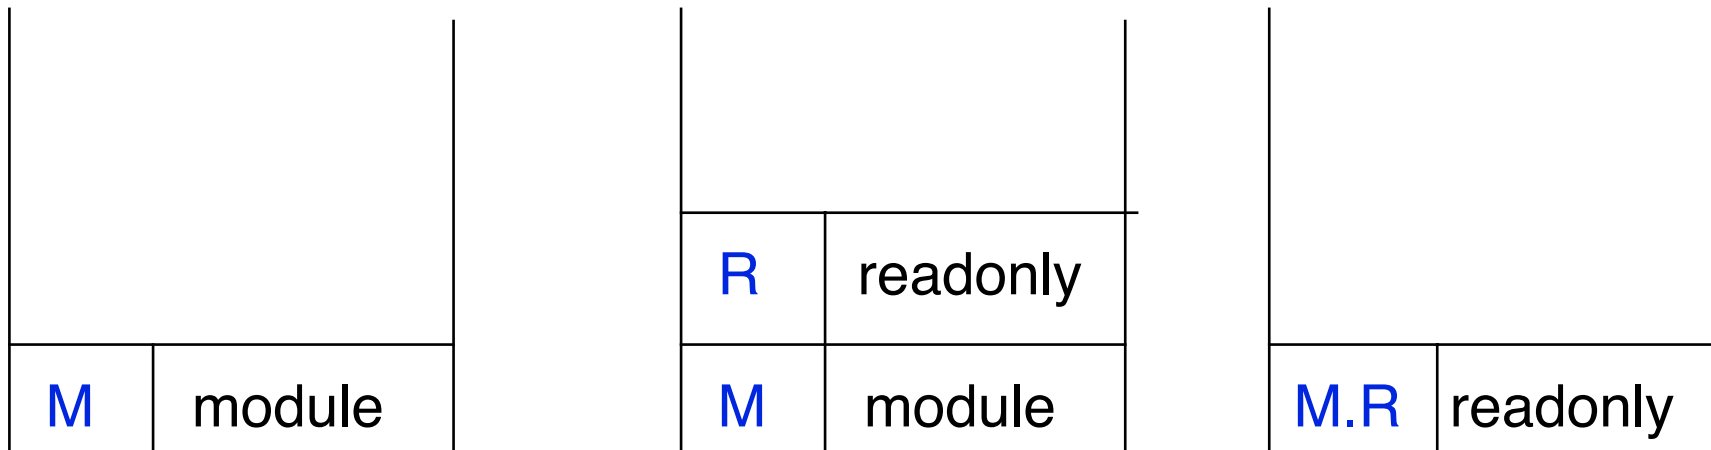

Minimum inherited access gives us the following:

# Symbol Stack - Access Calculation Example

- The Symbol Stack records the effective access attributes at each stage as we process the reference

(Note: the actual references are shown for clarity in the example - the stack does not actually store the reference expressions)

# Symbol Stack - Access Calculation Example 2

$F(X).Y$

where

$F$  is a function

$X$  is a variable

$Y$  is a field of the record (or object) returned by  $F$

We end up with the following:

# Symbol Stack - Access Calculation Example 2

<b>F</b>	function

<b>X</b>	var
<b>F</b>	function

<b>F(X)</b>	const

<b>Y</b>	var
<b>F(X)</b>	const

<b>F(X).Y</b>	const

(Note: the actual references are shown only for clarity - the stack does not actually store the reference expressions, only their **attributes**, such as access and memory address)

# Symbol Stack – Access Calculation

- Minimum access inheritance is a general rule, and applies well to OO languages such as **C++** and **Java** as well as to modular languages like **Turing** and **Ada**
- For example, access permissions of member variables generally follow minimum access inheritance rules - a **protected** variable of a superclass may not be exported as a **public** variable by the subclass
- However, minimum access does not apply in all cases
  - e.g., If  $p$  is a pointer in C, then  $*p$ , the variable pointed at by  $p$ , is an assignable variable even if  $p$  itself is a constant pointer

# Symbol Stack - Declaration Processing

- The **Symbol Stack** is also used to accumulate **declaration** information for a symbol until it is complete and can be entered in the **Symbol Table**
- Example:

```
var R : record
    var A : integer
    var B : integer
end record
```

R	var rec 0

A	var
R	var rec 0

B	var
A	var
R	var rec 0

R	var rec 2

# Symbol Stack - Declaration Processing

- Since types and initial values can be **expressions**, it's possible for the **Symbol Stack** to be used for **both** purposes at once
- Example:

**var A : M.T := F(X)**

<b>A</b>	var

<b>M</b>	module
<b>A</b>	var

<b>T</b>	type
<b>M</b>	module
<b>A</b>	var

<b>M.T</b>	type
<b>A</b>	var

<b>F</b>	function
<b>A</b>	var

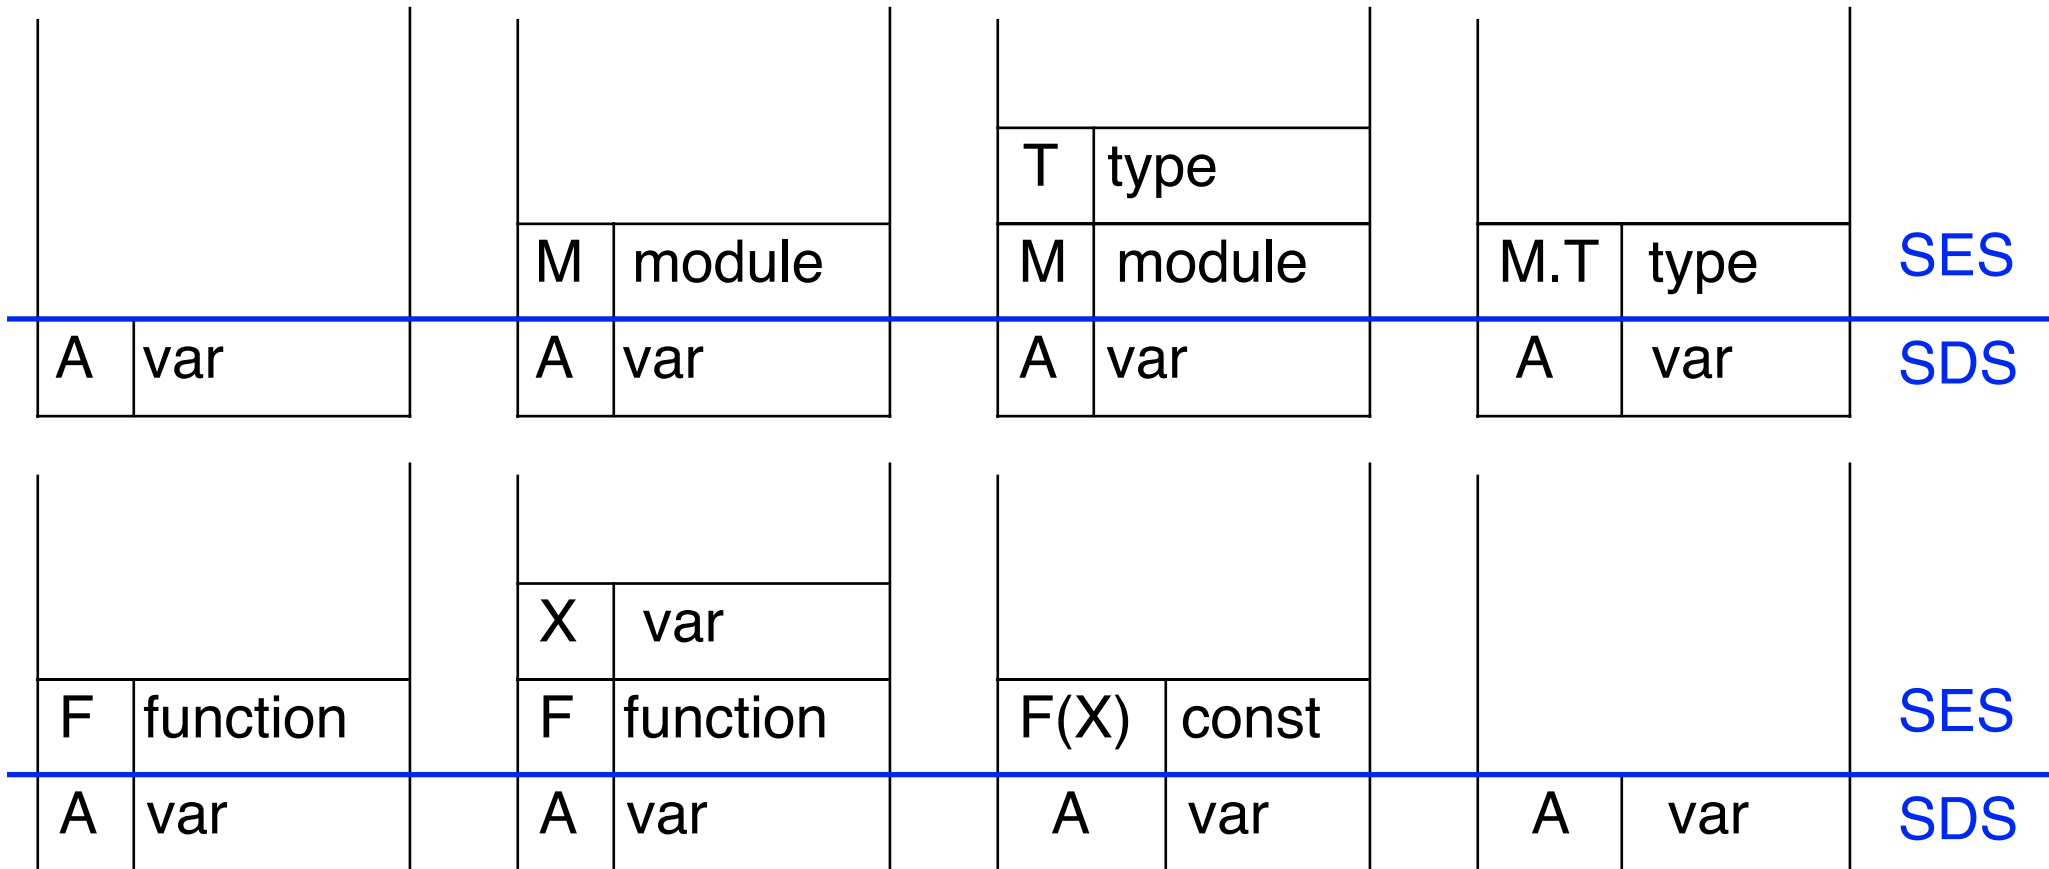

<b>X</b>	var
<b>F</b>	function
<b>A</b>	var

<b>F(X)</b>	const
<b>A</b>	var

<b>A</b>	var

# Symbol Stack - Declaration Processing

- Conceptually, the Symbol Stack has two parts -
  - the *Symbol Declaration Stack* (SDS), which processes declarations
  - the *Symbol Expression Stack* (SES), which processes references
- They don't interfere with one another since we can prove that the **SES** is always empty when we need to push or pop the **SDS**

# Symbol Declaration – Example

```
module M                1
  var R : record        2
    var X : N.T         3,4,5,6,7
    ...
  end record            8
...
end module
```

where **N** is a previously declared module exporting type **T**

1. push new entry for **M** (SDS)
2. push new entry for **R** (SDS)
3. push new entry for **X** (SDS)
4. push reference to module **N** (SES)
5. push reference to type **T** (SES)
6. resolve reference to **N.T** (SES)
7. Enter **X** into symbol table as type **N.T** (SES/SDS)
8. Enter **R** into symbol table with record type (SDS).

# Symbol Declaration – Example

M	module

R	var
M	module

X	var
R	var
M	module

N	module
X	var
R	var
M	module

T	type
N	module
X	var
R	var
M	module

N.T	type
X	var
R	var
M	module

SES  
SDS

R	var
M	module

M	module

# Summary

- **Simulation** in Semantic Analysis
  - We simulate execution like an **ES**, except compute types and attributes rather than values
  - The **Symbol Stack** computes attributes of symbol declarations and references
  - Because each use (declaration, expression) nests with respect to the other, this stack can be used for both purposes at once
- **Next time**
  - The **Type Stack**, Semantic Mechanisms
